Cyanobacteria harmful algal blooms (cHABs) are associated with a wide range of adverse health effects that stem mostly from the presence of cyanotoxins. To help protect against these impacts, several health advisory levels have been set for some toxins. In particular, one of the more common toxins, microcystin, has several advisory levels set for drinking water and recreational use. However, compared to other water quality measures, field measurements of microcystin are not commonly available due to cost and advanced understanding required to interpret results. Addressing these issues will take time and resources. Thus, there is utility in finding indicators of microcystin that are already widely available, can be estimated quickly and *in situ*, and used as a first defense against high levels of microcystin. In particular, chlorophyll *a* is very commonly measured, can be estimated *in situ*, and has been shown to be positively associated with microcystin. In this paper, we use this association to provide estimates of chlorophyll *a* concentrations that if exceeded would be indicative of a higher probability of exceeding select health advisory concentrations for microcystin-LR. Using the 2007 National Lakes Assessment and a conditional probability approach, we identify chlorophyll *a* concentrations that are more likely than not to be associated with an exceedance of a microcystin health advisory level. We look at the recent US EPA health advisories for drinking water as well as the World Health Organization levels for drinking water and recreational use. For the specific advisory microcystin concentrations of 0.3, 1, 1.6, and 2, we find chlorophyll *a* concentrations of 0.07, 0.07, 2.79, and 11.36, respectively. When managing for these various microcystin levels, exceeding these reported chlorophyll *a* concentrations should be a trigger for further testing and possible management action.

1 Introduction

Over the last decade or so numerous events and legislative activities have raised the public awareness of harmful algal blooms (Rinta-Kanto et al. 2009, HABHRCA 2014, Jetoo et al. 2015), and in response the US Environmental Protection Agency (USEPA) has recently released suggested microcystin-LR (one of the more common toxins) concentrations that would trigger health advisories (McElhiney and Lawton 2005, Zurawell et al. 2005, USEPA 2015). Additionally, the World Health Organization (WHO) has had proposed advisory levels for drinking water and a range of recreational risk levels (Chorus and Bartram 1999, Organization 2003). While these levels and associated advisories are likely to help

mitigate the impacts from harmful algal blooms, they are not without complications.

One of these complications is that they rely on available measurements of microcystin-LR. While laboratory testing remains the gold standard for quantifying microcystin-LR concentrations in water samples, several field test kits have been developed. Even though field tests provide a much needed means for rapid assessment, they are not yet widely used and are moderately expensive (approximately \$150-\$200 depending on specific kit) with a limited shelf life (typically one year) (James et al. 2011, Aranda-Rodriguez et al. 2015). Additionally, each technique requires nuanced understanding of the detection method (e.g., limit of detection, specific microcystin variants being measured, and sampling protocol).

Fortunately, microcystin-LR has been shown to be associated with several other, more commonly measured and well understood components of water quality that are readily assessed in the field. For instance, there are small or hand held fluorometers that measure chlorophyll *a*. Additionally, chlorophyll *a* is a very commonly measured component of water quality that is also known to be positively associated with microcystin-LR concentrations (Pip and Bowman 2014, Yuan et al. 2014). Yuan et. al (2014) explore these associations in detail and control for other related variables. In their analysis they find that total nitrogen and chlorophyll *a* show the strongest association with microcystin. Furthermore, they identify chlorophyll *a* and total nitrogen concentrations that are associated with exceeding 1 $\mu\text{g/L}$ of microcystin. Given these facts, it should be possible to identify chlorophyll *a* concentrations that would be associated with the new USEPA Microcystin-LR health advisory levels for drinking water. Identifying these associations would provide another tool for water resource managers to help manage the threat to public health posed by CHABs and would be especially useful in the absence of microcystin-LR concentrations.

In this paper we build on past efforts and utilize the National Lakes Assessment (NLA) data and identify chlorophyll *a* concentrations that are associated with higher probabilities of exceeding several microcystin-LR health advisory concentrations (Chorus and Bartram 1999, USEPA 2009, 2015). We add to past studies by exploring associations with newly announced advisory levels and by also applying a different method, conditional probability analysis. Utilizing different methods strengthens the evidence for suggested chlorophyll *a* levels that are associated with increased risk of exceeding

the health advisory levels as those levels are not predicated on a single analytical method. So that others may repeat or adjust this analysis, the data, code, and this manuscript are freely available via <https://github.com/USAPE/microcystinchla>.

2 Methods

2.1 Data

We used the 2007 NLA water quality and microcystin-LR concentration data (USEPA 2009). These data represent a snapshot of water quality from the summer of 2007 for the conterminous United States. Data on chlorophyll *a* and microcystin-LR concentrations are available for lakes.

2.2 Conditional Probability Analysis

We used a conditional probability analysis (CPA) approach to explore associations between chlorophyll *a* concentrations and World Health Organization (WHO) and USEPA microcystin-LR health advisory levels (Paul and Munns 2011). Many levels have been suggested (Table 1), but lakes with higher microcystin-LR concentrations in the NLA were rare. Only 1.16 % of lakes sampled had a concentration greater than 10. Thus, for this analysis we focus on the microcystin concentrations that are better represented in the NLA data. These were the USEPA children’s drinking water advisory level of 0.3 $\mu\text{g/L}$ (USEPA Child), the WHO drinking water advisory level of 1 $\mu\text{g/L}$ (WHO Drinking), the USEPA adult drinking water advisory level of 1.6 $\mu\text{g/L}$ (USEPA Adult), and the WHO recreational, low probability of effect advisory level of 2 $\mu\text{g/L}$ (WHO Recreational).

Conditional probability analysis provides information about the probability of observing one event given another event has also occurred. For this analysis, we used CPA to examine how the conditional probability of exceeding one of the health advisories changes as chlorophyll *a* increases in a lake. We expect to find higher chlorophyll *a* concentrations to be associated with higher probabilities of exceeding the microcystin-LR health advisory levels. We also calculated bootstrapped 95% confidence intervals (CI) using 1000 bootstrapped samples. Thus, to identify chlorophyll *a* concentrations of concern we

88 identify the value of the upper 95% CI across a range of conditional probabilities of exceeding each
89 health advisory level. As both microcystin-LR and chlorophyll *a* values were highly skewed right, a
90 log base 10 transformation was used. Additional details of the specific implementation are available at
91 <https://github.com/USEPA/microcystinchla>. A more detailed discussion of CPA is beyond the scope of
92 this paper, but see Paul et al. (2005) and Hollister et al. (2008) for greater detail.

93 3 Results

94 In the 2007 NLA, microcystin-LR concentrations ranged from 0.05 to 225 $\mu\text{g/L}$. Microcystin-LR
95 concentrations of 0.05 $\mu\text{g/L}$ represent the detection limits. Any value greater than that indicates the
96 presence of microcystin-LR. Of those lakes with microcystin, the median concentration was 0.51 and
97 the mean was 3.17. Of all lakes sampled, 21% of lakes exceeded the USEPA Child level, 8.8% of lakes
98 exceeded the USEPA Adult level, 11.7% of lakes exceeded the WHO Drinking level, and 7.3% of lakes
99 exceeded the WHO Recreational level. For chlorophyll *a*, the range was 0.07 to 936 $\mu\text{g/L}$. All lakes had
100 reported chlorophyll *a* concentrations that exceeded detection limits. The median concentration was 7.79
101 $\mu\text{g/L}$ and the mean was 29.63 $\mu\text{g/L}$. The associations between chlorophyll *a* and the upper confidence
102 interval across a range of conditional probability values is shown in Table 2. Specific chlorophyll *a* that
103 are associated with greater than even odds of exceeding the advisory levels were 0.07, 0.07, 2.79, and
104 11.36 for 0.3, 1.0, 1.6 and 2.0 $\mu\text{g/L}$ advisory levels, respectively (Table 2 & Figure 2).

105 4 Discussion

106 The association between Log10 microcystin-LR and Log10 chlorophyll *a* shows a wedge pattern (Figure
107 1). This indicates that higher concentrations of microcystin-LR almost always co-occur with higher
108 concentrations of chlorophyll *a* yet the inverse is not true. Higher chlorophyll *a* is not necessarily
109 predictive of higher microcystin-LR concentrations; however, chlorophyll *a* may be predictive of the
110 probability of exceeding a certain concentration.

111 This is the case as the probability of exceeding each of the four tested health advisory levels increases

112 as a function of chlorophyll *a* concentration (Figure 2). We use this association to identify chlorophyll *a*
113 concentrations that are associated with greater than even odds of exceeding a given health advisory
114 level (Table 2). These represent 99.9%, 99.9%, 77%, and 43.8% of sample lakes for the USEPA Child,
115 the WHO Drinking, the USEPA Adult, and the WHO recreational levels, respectively.

116 Furthermore, the chlorophyll *a* cutoffs may be used to predict whether or not a lake exceeds the
117 microcystin-LR health advisories. Doing so allows us to compare the accuracy of the prediction as well
118 as evaluate false negatives. Total accuracy of the four cutoffs predicting microcystin-LR exceedances
119 were 21% for the USEPA children’s advisory, 12% for the WHO drinking water advisory, 31% for the
120 USEPA adult advisory and, 61% for the WHO recreational advisory (Tables 3, 4, 5, & 6). However,
121 total accuracy is only one part of the prediction performance with which we are concerned.

122 When using the chlorophyll *a* cutoffs as an indicator of microcystin-LR exceedances, the error that
123 should be avoided is predicting that no exceedance has occurred when in fact it has. In other words,
124 we would like to avoid Type II errors and minimize the proportion of false negatives. For the four
125 chlorophyll *a* cut-offs we had a proportion of false negatives of 0%, 0%, 0% and , 1% for the U.S EPA
126 childrens drinking water, the WHO drinking water, the USEPA adult drinking water, and the WHO
127 recreational advisories, respectively. In each case we miss less than 10% of the lakes that are in fact
128 exceeding the microcystin-LR advisory.

129 There are numerous possible uses for the chlorophyll *a* and microcystin-LR advisory cut-off values.
130 First, in the absence of microcystin-LR measurements, exceedence of the chlorophyll *a* concentrations
131 could be a trigger for further actions. Given that there is uncertainty around these chlorophyll *a* cutoffs
132 the best case scenario would be to monitor for chlorophyll *a* and in the event of exceeding a target
133 concentration take water samples and have those samples tested in a lab for microcystin-LR.

134 A second potential use is to identify possible bloom events from historical data. As harmful algal blooms
135 are made up of many species and have various mechanisms responsible for adverse impacts (e.g. toxins,
136 hypoxia, odors), there is no single definition of a bloom. For cHABs one approach has been to identify
137 an increase over a baseline concentration of phycocyanin (Miller et al. 2013). This is a useful approach
138 for targeted studies, but phycocyanin is also not always available and measures the predominance of
139 cyanobacterial pigments and not toxins. Using our chlorophyll *a* cutoffs provides a value that is more

140 directly associated with microcystin-LR and can be used to classify lakes, from past surveys, as having
141 bloomed.

142 Lastly, using chlorophyll *a* is not meant as a replacement for testing of microcystin-LR. It should be
143 used when other, direct measurements of cyanotoxins are not available. In those cases, which are likely
144 to be common at least in the near future, using a more ubiquitous measurement, such as chlorophyll *a*
145 will provide a reasonable proxy for the probability of exceeding a microcystin-LR health advisory level
146 and provide better protection against adverse effects in both drinking and recreational use cases.
